ABSTRACT

We present the largest Wiener reconstruction of the cosmic density field made to date. The reconstruction is based on the Sloan Digital Sky Survey (SDSS) data release 6 covering the northern Galactic cap. We use a novel supersampling algorithm to suppress aliasing effects and a Krylov-space inversion method to enable high performance with high resolution. These techniques are implemented in the ARGO computer code. We reconstruct the field over a 500 Mpc cube with Mpc grid resolution while accounting for both the angular and the radial selection functions of the SDSS, and the shot noise giving an effective resolution of the order of ∼10 Mpc. In addition, we correct for the redshift distortions in the linear and non-linear regimes in an approximate way. We show that the commonly used method of inverse weighting the galaxies by the corresponding selection function heads to excess noise in regions where the density of the observed galaxies is small. It is more accurate and conservative to adopt a Bayesian framework in which we model the galaxy selection/detection process to be Poisson binomial. This results in heavier smoothing in regions of reduced sampling density. Our results show a complex cosmic web structure with huge void regions indicating that the recovered matter distribution is highly non-Gaussian. Filamentary structures are clearly visible on scales of up to ∼20 Mpc. We also calculate the statistical distribution of density after smoothing the reconstruction with Gaussian kernels of different radii $r_s$ and find good agreement with a lognormal distribution for $10 \text{ Mpc} \lesssim r_s \lesssim 30 \text{ Mpc}$.

1 INTRODUCTION

Measuring the large-scale structure (LSS) of the Universe has become a major task in cosmology in recent years. The relics of the seed fluctuations, originating from the inflationary phase of the early Universe, are mainly encoded in the linear regime of the LSS in which structure formation has not significantly degraded the primordial phase information. In particular, there has recently been a focus on measuring the baryon acoustic signal imprinted in the galaxy distribution which has been suggested as a powerful standard ruler for our Universe (see e.g. Eisenstein 2005).

Upcoming and ongoing galaxy redshift surveys such as DEEP2 or Baryon Oscillation Spectroscopic Survey (BOSS) will cover higher and higher redshifts (see e.g. Davis et al. 2005; Schlegel et al. 2007). They are designed to trace complex structures in the Universe and to study the environment of galaxies and their evolution.

We carry a reconstruction of the density field dealing with statistical and systematic errors of the galaxy distributions with the ARGO computer code described in (Kitaura & Enßlin 2008). ARGO is a high-performance implementation of a three-dimensional Wiener filter (WF), permitting treatments of an inhomogeneous and incomplete window function acting on the galaxy distribution. It exploits
the power of fast Fourier transforms (FFTs) and iterative Krylov-space-based inversion schemes for the otherwise intractable data inversion step.

Reconstructions permit us to characterize the LSS, helping to deepen our understanding of structure formation, to gain insight into the physical processes involved and to construct signal templates for the detection of weak physical effects. These can be used to study the Cosmic Microwave Background (CMB) and to reveal signals ranging from the Integrated Sachs–Wolfe effect (see e.g. Frommert, Enßlin & Kitaura 2008), over the Sunyaev–Zel’dovich effect in the diffuse gas, to metal absorption lines. An interesting further application would be to constrain the bias between luminous and dark matter using reconstructions made by ARGO and correlating them with simulations and reconstructions of the matter distribution coming from other observables such as weak lensing, Lyman α forest etc. Topological studies could be made from the reconstructed data, leading to a geometrical characterization of the actual LSS (see e.g. Sheth & Sahni 2005). It is also interesting to study how the physical properties of galaxies depend on their large-scale environment (Li et al. 2006b; Lee & Lee 2008; Lee & Li 2008). The reconstructed structures of a galaxy catalogue can be traced back in time with various methods, like those based on the Zel’dovich (1970) approximation (see e.g. Nusser & Dekel 1992). These early matter density fluctuations can be used as initial conditions for N-body simulations. The results of such a constrained simulation have a wide application in structure formation theory (see e.g. Mathis et al. 2002). A joint estimation of the matter field and its power spectrum would also be a natural next step given the technology we develop below (for similar work in CMB analysis, see e.g. Jewell, Levin & Anderson 2004; Wandelt, Larson & Lakhminarayan 2004; Eriksen et al. 2007).

We present the first application of ARGO to observational data. In particular, we have applied our method to recover the galaxy density field based on data from Sample dr6fix of the New York University Value Added Catalogue (NYU-VAGC), which was constructed from the Sloan Digital Sky Survey (SDSS; York et al. 2000) Data Release 6 (DR6; Adelman-McCarthy et al. 2008). This leads to the largest Wiener reconstruction of the LSS made so far effectively requiring the inversion of a matrix with about $10^8 \times 10^8$ entries. The use of optimized iterative inversion schemes within an operator formalism (see Kitaura & Enßlin 2008) together with a careful treatment of aliasing effects (see Jasche, Kitaura & Enßlin 2009) permits us to recover the overdensity field on Mpc scales (for previous Wiener reconstructions, see Fisher, Scharf & Lahav 1994; Hoffman 1994; Lahav et al. 1994; Lahav 1994; Zaroubi et al. 1995; Fisher et al. 1995; Webster, Lahav & Fisher 1997; Zaroubi, Hoffman & Dekel 1999; Schmoldt et al. 1999; Erdogdu et al. 2004, 2006). Note that alternative density reconstruction techniques such as Voronoi and Delaunay tessellations (see e.g. Icke & van de Weygaert 1991; Ebeling & Wiedenmann 1993; Zaninetti 1995; Bernardadeu & van de Weygaert 1996; Doroshkevich, Gottlober & Madsen 1997; Meurs & Wilkinson 1999; Kim et al. 2000; Schaap & van de Weygaert 2000; van de Weygaert & Schaap 2001; Ramella et al. 2001; Panko & Flin 2004; Zaninetti 2006) are tuned to optimally represent the density field from a geometrical point of view, but are not explicit in the statistical assumptions made on the galaxy or matter distribution, which is an important aspect of our analysis here.

We investigate in detail the statistical problem of finding an expression for a noise covariance which includes the survey angular and radial selection functions. The expression we find assumes a binomial model for the galaxy selection/detection process.

We show that including our proposed noise covariance matrix in the WF leads to a more conservative reconstruction of matter structures than using the inverse weighting (IW) scheme. We also compare the linear WF expression which is derived from a least-squares approach and the non-linear WF which uses a signal-dependent noise covariance (see appendix A in Kitaura & Enßlin 2008). The latter shows to be even more conservative than the linear WF since it strongly suppresses the cells with higher number counts.

Due to the fine mesh of the reconstruction ($\sim 1$ Mpc), a treatment of the redshift distortion in the linear and non-linear regimes is required. We choose a redshift distortion deconvolution method, as presented by Erdogdu et al. (2004), which aims to correct in both regimes. This treatment only corrects the power and neglects any phase information. For this reason, the effective resolution of the reconstruction is lower than the resolution of the grid ($\sim 10$ Mpc).

Our paper is structured as follows. We start by describing the input galaxy sample of the SDSS DR6 in Section 2. Then we present the methodology used to perform an estimation of the matter field (Section 3). In detail, the galaxy distribution is first transformed into the comoving frame (Section 3.1.1) and then assigned to a grid using our newly developed supersampling method (described in Jasche et al. 2009) to correct for aliasing effects, ensuring a correct spectral representation of the galaxy distribution even up to the highest modes contained in the grid (Section 3.1.2). Completeness on the sky and radial galaxy selection function are then translated into a three-dimensional mask, which will be part of the response operator used in the filtering step (Section 3.1.3). Then, an observed galaxy overdensity field is calculated which fulfils the statistical requirements we want to impose on the matter field (Section 3.2). Taking the observed galaxy field as the data vector we finally apply a Wiener-filtering step with the ARGO computer code (Section 3.3.1) followed by a deconvolution step, effectively correcting for the redshift distortion (Section 3.3.2). Here, we distinguish between a linear WF expression which is derived from a least-squares approach and a non-linear WF which uses a signal-dependent noise covariance. Both WF formulations are tested with mock data and quantitatively compared to a simple procedure in which the galaxies are inverse weighted with the completeness, then gridded and finally smoothed to give a matter field estimate.

We present a reconstruction of the density field for the DR6 main sample in Section 5. First, we analyse the survey sky mask (Section 5.1). Results for the Sloan Great Wall are then presented in detail. Some other prominent structures, for example the Coma, the Leo and the Hercules clusters, are also discussed (Section 5.2) together with the detection of a large void region (Section 5.3). The proper implementation of the filter enables us to deal with complex masks which include unobserved regions. We demonstrate the improved detection of overdensity regions close to edges of the mask and the prediction of structures in gaps, as demonstrated by comparing with data from the Data Release 7 (DR7) where these gaps are filled (Section 5.4). In Section 5.5, we analyse the statistical distribution of the density field and find good agreement with a lognormal distribution for smoothing radii in a Gaussian filter in the range $10 \text{Mpc} \lesssim r_s \lesssim 30 \text{Mpc}$. Finally, we make a summary of the work and present our conclusions and future outlook.

### 2 INPUT GALAXY SAMPLE

In this study, we use data from the DR6 (Adelman-McCarthy et al. 2008) of the SDSS (York et al. 2000). The survey contains images of a quarter of the sky obtained using a drift-scan camera (Gunn et al. 1998) in the $u$, $g$, $r$, $i$, $z$ bands (Fukugita et al. 1996; Smith
et al. 2002; Ivezić et al. 2004), together with spectra of almost a million objects obtained with a fibre-fed double spectrograph (Gunn et al. 2006). Both instruments were mounted on a special-purpose 2.5 metre telescope (Gunn et al. 2006) at Apache Point Observatory. The imaging data are photometrically (Hogg et al. 2001; Tucker et al. 2006) and astrometrically (Pier et al. 2003) calibrated and were used to select spectroscopic targets for the main galaxy sample (Strauss et al. 2002), the luminous red galaxy sample (Eisenstein et al. 2001) and the quasar sample (Richards et al. 2002). Spectroscopic fibres are assigned to the targets using an efficient tiling algorithm designed to optimize completeness (Blanton et al. 2003c). The details of the survey strategy can be found in York et al. (2000) and an overview of the data pipelines and products is provided in the Early Data Release paper (Stoughton et al. 2002). More details on the photometric pipeline can be found in Lupton et al. (2001) and on the spectroscopic pipeline in SubbaRao et al. (2002).

We take data from Sample dr6fix of the NYU-VAGC. This is an update of the catalogue constructed by Blanton et al. (2005) and is based on the SDSS DR6 data and publicly available selection masks.2 Starting from Sample dr6fix, we construct a magnitude-limited sample of galaxies with spectroscopically measured redshifts in the range 0.001 < z < 0.4, r-band Petrosian apparent magnitudes 14.5 < m < 17.6 and r-band absolute magnitudes −23 < M_{r,z} < −17. Here m is corrected for Galactic extinction, and the apparent magnitude limits are chosen in order to get a sample that is uniform and complete over the entire area of the survey. The absolute magnitude M_{r,z} is corrected to its z = 0.1 value using the K-correction code of Blanton et al. (2003a) and the luminosity evolution model of Blanton et al. (2003b). We also restrict ourselves to galaxies located in the main area of the survey in the northern Galactic cap, excluding the three survey strips in the southern cap, i.e. we include galaxies with right ascension (α) and declination (δ) in the following ranges: 105° < α < 270° and −5° < δ < 70°. In addition, we considered only galaxies which are inside a comoving cube of side 500 Mpc (with equal side lengths: L_x × L_y × L_z), as we describe below. These restrictions result in a final sample of 253 818 galaxies.

In order to correct for incompleteness in our spectroscopic sample, we need to have complete knowledge of its selection effects. A detailed account of the observational selection effects accompanies the NYU-VAGC release. These include two parts: a mask on the sky and a radial selection function along the line of sight. The mask shows which areas of the sky have been targeted and which have not, either because they are outside the survey boundary, because they contain a bright confusing source or because observing conditions were too poor to obtain all the required data. The effective area of the survey on the sky defined by this mask, is 5314 deg² for the sample we use here. It is divided into a large number of smaller subareas, called polygons, for each of which the NYU-VAGC lists a spectroscopic completeness. This is defined as the fraction of the photometrically defined target galaxies in the polygon for which usable spectra were obtained. The average completeness over our sample galaxies is 0.86. The radial selection function gives the fraction of galaxies in the absolute magnitude range being considered (−23 < M_{r,z} < −17 in our case) that are within the apparent magnitude range of the sample (14.5 < m ≤ 17.6 in our case) at a given redshift.

In certain cases, we also work with a sample of galaxies drawn from SDSS DR7 (Abazajian & Sloan Digital Sky Survey 2008) for which the galaxy positions, redshifts and fluxes are publicly available from the SDSS website3 but the survey completeness as described above was not released at the moment this work started. With this sample we apply only a gridding scheme and a subsequent Gaussian smoothing, without accounting for any selection effects, in order to qualitatively check for overdense regions present in the gap in the SDSS DR6.

3 METHODOLOGY

In this section, we describe the main algorithms required to perform a WF reconstruction of the matter field as described in Kitaura & Enßlin (2008) (see also the pioneering works Wiener 1949; Rybicki & Press 1992; Zaroubi et al. 1995). We start with the preparation of the data followed by a filtering step and a final deconvolution. Detailed descriptions of the methodology used for each step are described in the following subsections.

3.1 Preparation of the data

Reconstructing a signal like the matter density field from the observed galaxy sample requires a model which relates the underlying matter field to the galaxy distribution. This model will define the inverse problem, which can be solved with a reconstruction algorithm. In this subsection, we describe how to prepare the input data in such a way that it is consistent with the data model underlying the ARGO code.

3.1.1 Transformation of the data into comoving coordinates

To apply a reconstruction algorithm which uses the correlation function in a comoving space, we first have to transform the redshift distances into comoving distances for each galaxy by performing the integral:

\[ r = \int \frac{dz}{cH(z)} \]

with H(z) being the Hubble parameter given by

\[ H(z) = H_0 \sqrt{\Omega_m(1+z)^3 + \Omega_k(1+z)^2 + \Omega_{\Lambda}} \]

where we chose the concordance \( \Lambda \) cold dark matter (ΛCDM) cosmology with \( \Omega_m = 0.24, \Omega_k = 0 \) and \( \Omega_{\Lambda} = 0.76 \) (Spergel et al. 2007). In addition, we assumed a Hubble constant: \( H_0 = 73 \) km s⁻¹ Mpc⁻¹ with \( h = 73 \).

With this definition, the three-dimensional galaxy positions (X, Y, Z) in the comoving space are calculated as follows:

\[
X = r \cos(\delta) \cos(\alpha) \\
Y = r \cos(\delta) \sin(\alpha) \\
Z = r \sin(\delta)
\]

3 http://www.sdss.org/dr7

4 Not to be confused with the r-band.
3.1.2 Supersampling step

Now, we can sort the galaxies into a grid with a supersampling scheme, which will permit us to apply a reconstruction scheme based on FFTs. The much lower computational costs of FFTs permit us to tackle much more ambitious matter reconstructions than have been attempted previously with Wiener-filtering techniques. The main difficulty in signal processing via FFT techniques arises from the need to represent a continuous signal which extends to infinity on a finite discrete grid. Various methods to approximate the real continuous signal by a discrete representation have been proposed in the literature, e.g. nearest grid point (NGP), cloud in cell (CIC) or triangular shaped clouds (TSC; see e.g. Hockney & Eastwood 1981). However, all of these methods are only approximations to the ideal low-pass filter and introduce discretization artefacts such as aliasing. For a detailed discussion, see e.g. Hockney & Eastwood (1981), Jing (2005), Cui et al. (2008) and Jasche et al. (2009). In recent years a number of methods have been proposed to correct for these artefacts, especially for the purpose of power-spectrum estimation (Jing 2005; Cui et al. 2008). However, common methods to suppress these artefacts in the discretized signals tend to be numerically expensive.

To circumvent this problem, Jasche et al. (2009) proposed a supersampling technique, which is able to provide discrete signal representations with strongly suppressed aliasing contributions at reasonable computational cost. This method relies on a two-step filtering process, where in the first step the signal is pre-filtered by sampling the signal via the TSC method to a grid with twice the target resolution. In our case, we use a 10244 grid. In a second step the ideal discrete low-pass filter is applied to the pre-filtered signal, allowing us to sample the low-pass-filtered field at the lower target resolution. In this fashion, we obtain an aliasing free signal sampled at a target resolution of 5123 cells (with an equal number of cells in each axis: $N_x 	imes N_y 	imes N_z$).

Let us define the observed galaxy sample as a point source distribution $n_s^o(s)$ with coordinate $s$:

$$n_s^o(s) = \sum_{i=1}^{N_o^o} \delta_D(s-s_i),$$

with $N_o^o$ being the total observed galaxy number count and $\delta_D$ the Dirac-delta function. The process of putting the galaxies on a regular grid is equivalent to a convolution in a real space followed by a grid-point selection step according to Hockney & Eastwood (1981):

$$n^o(s) = \Pi\left(\frac{s}{H}\right) \int ds' K_S(s-s') n_s^o(s'),$$

with $\Pi(r) = \sum_{n \in Z} \delta_D(s - n)$, $H$ being the grid spacing and $K_S$ the supersampling kernel. We define the resulting field as the observed galaxy number density $n^o(s)$. The observed galaxy number density is a function of the Cartesian position in a comoving space, but includes redshift distortion. For this reason, we say that the distribution is in a redshift space denoted by the coordinate $s$.

3.1.3 Calculation of the three-dimensional mask: completeness on the sky and selection function

To define the data vector, we need to model the three-dimensional mask. We do this by processing the two-dimensional sky mask in several steps. First, the sky mask or completeness on the sky $w_{SKY}(\alpha, \delta)$ is evaluated using the survey mask provided in Sample dr6fix of the NYU-VAGC (see Section 2) on an equidistant $\alpha \times \delta$ grid with 165 000 × 75 000 cells having a resolution of 36 arcsec in both right ascension and declination (see panel a in Fig. 6). Then, we project the sky mask on a comoving Cartesian $X \times Y \times Z$ grid containing 5123 cells.

This is done with the transformation given by equation (3) taking projected values of the mask every 0.25 Mpc in the radial direction which are then assigned to the grid using the NGP method and normalized by the number of mask counts in that grid cell. The analogous procedure is done with the radial completeness $w_{r}(z)$, i.e. the selection function which is available as a function of redshift.

Finally, we obtain the three-dimensional mask $w(s)$ as a product of the projected two-dimensional mask, i.e. the completeness on the sky $w_{SKY}(\alpha, \delta)$, and the projected selection function $w_{r}(s)$ (see Fig. 1, and Figs 6(a), 8(a), 9(a), 9(e) and 10(a) in Section 5). We define $w(s) \leq 1$.

3.2 Definition of the data model

Let us define the observed galaxy overdensity field as

$$\delta^o(s) \equiv \frac{n^o(s)}{\bar{n}} - 1,$$

with $\bar{n}$ being the mean galaxy number density.

The mean galaxy number density on the grid $\bar{n}$ is defined by the quotient of the total number of observed galaxies $N_o^o$ and the observed volume $V_o$. Note that this assumes that the observed volume is a fair sample of the Universe. We can then write

$$\bar{n} \equiv \frac{N_o^o}{V_o} = \frac{\sum_{i=1}^{N_{cells}} N_{cell}^i}{\int \! dr \, w(r)},$$

with $N_{cell}^i$ being the number of observed galaxies at cell $i : N_o^o \equiv \sum_{i=1}^{N_{cells}} N_{cell}^i$, $N_{cells}$ being the total number of cells and the observed volume being defined by the integral: $V_o \equiv \int \! dr \, w(r)$. The relation between the expected galaxy number density in a small volume $\Delta V$
around position \( \mathbf{r} \) \( \rho_d(\mathbf{r}) \) and the mean galaxy number density in the whole volume under consideration \( V \) is given by

\[
\rho_d(\mathbf{r}) = \bar{\rho}(1 + \delta_d(\mathbf{r})),
\]

where \( \delta_d(\mathbf{r}) \) is the galaxy overdensity field, which describes the spatial density distribution of galaxies. Here we assume that effects due to galaxy evolution are negligible in the observed region and, especially, that the mean number density is redshift independent.

The observed quantity \( \delta^o_g(\mathbf{s}) \) defined in equation (6) has to be related to the signal, we seek to recover, via a data model. This relation is to be inverted by the reconstruction algorithm.

### 3.2.1 Physical model

In this section, we describe the physical model which will enable us to apply linear reconstruction methods and obtain an estimate of the matter field valid on large scales (> 1 Mpc). Let us assume a continuous matter field \( \delta_m(\mathbf{r}) \) in a comoving space \( \mathbf{r} \) as well as a continuous galaxy field \( \delta_g \). We model the actual galaxies as being Poisson distributed according to this field with an expectation density of \( \bar{\rho}(1 + \delta_d(\mathbf{r})) \). In general, the relation between the galaxy overdensity field \( \delta_d \) and the underlying matter field \( \delta_m \) will be given by a non-local and non-linear bias operator. However, the formalism we present here, without any further development, allows us to account only for a non-local linear translation-invariant bias operator \( \mathbf{B}(\mathbf{r} - \mathbf{r}') \) of the form

\[
\delta_g(\mathbf{r}) = \int d\mathbf{r}' \mathbf{B}(\mathbf{r} - \mathbf{r}')\delta_m(\mathbf{r}').
\]

Note that this linear operator is known to fail at least at sub-Mpc scales. Several non-local biasing models are described in the literature, which are mainly used for the sake of the shape of the power spectrum on large scales (Tegmark et al. 2004; Hamann et al. 2008). We will carry this general bias through the algebraic calculations. However, in this work we consider the galaxy field to be a fair sample of the matter field. Thus, we assume the special case of a linear constant bias equal to unity: \( \mathbf{B}(\mathbf{r}, \mathbf{r}') = \delta_m(\mathbf{r} - \mathbf{r}') \), so that \( \delta_g = \delta_m \). Nevertheless, any non-local bias scheme of the form of equation (9) can be adapted without the need to repeat the filtering. We show that one can easily deal with non-local bias models in a final deconvolution step (see equation 30). As a result, various posterior biasing assumptions can be applied based on this reconstruction to test different biasing models.

We will also assume the existence of a redshift distortion operator\(^6\) \( Z(\mathbf{s}, \mathbf{r}) \), which transforms the density field from a real space into a redshift space. Note that the redshift distortion operator cannot be a linear operator, since it depends on the matter field \( \delta_m(\mathbf{r}) \). However, we will approximate it with a linear redshift distortion operator \( Z(\mathbf{s}, \mathbf{r}) \) here

\[
\delta_g(\mathbf{s}) = \int d\mathbf{r} Z(\mathbf{s}, \mathbf{r})\delta_g(\mathbf{r}),
\]

and postpone a matter-field dependent treatment, sampling the peculiar velocity field as proposed in (Kitaura & Enßlin 2008), for later work.

Let us further assume an additive noise term resulting in a data model for the observed galaxy overdensity as

\[
\delta^o_g(\mathbf{s}) = w(\mathbf{s}) \int d\mathbf{r} Z(\mathbf{s}, \mathbf{r}) \int d\mathbf{r}' \mathbf{B}(\mathbf{r} - \mathbf{r}')\delta_m(\mathbf{r}') + \epsilon(\mathbf{s}).
\]

with \( \epsilon \) being the noise term. The corresponding vector representation of the data model can be approximated as

\[
\mathbf{d}^o_g(\mathbf{s}) = \mathbf{W}_g Z(\mathbf{s}, \mathbf{r}) \mathbf{B} \delta_m + \epsilon(\mathbf{s}),
\]

with the subscripts \( r \) and \( s \) denoting the real space and redshift space, respectively. The response operator can be defined by

\[
\mathbf{R}_g = \mathbf{W}_g Z(\mathbf{s}, \mathbf{r}) \mathbf{B},
\]

with \( \mathbf{W}_g \) being the three-dimensional mask operator defined in continuous space by \( W(s, s') = w(s)\delta_D(s - s') \), \( Z(\mathbf{s}) \) being the redshift distortion operator and \( \mathbf{B} \) being the bias operator. Now we need to specify a model for the noise term.

### 3.2.2 Statistical model

Assuming that the galaxy distribution is generated by an inhomogeneous Poissonian distribution, the number galaxy count \( N_c \) within a volume \( \Delta V \) around position \( \mathbf{r} \) is distributed as

\[
N_c(\mathbf{r}) \sim P_{\text{Pois}}(N_c(\mathbf{r})|\bar{\lambda}(\mathbf{r}))
\]

with

\[
P_{\text{Pois}}(N_c(\mathbf{r})|\bar{\lambda}(\mathbf{r})) = \frac{(\bar{\lambda}(\mathbf{r})^{N_c(\mathbf{r})}) \exp(-\bar{\lambda}(\mathbf{r}))}{N_c(\mathbf{r})!},
\]

where the expected number of galaxy counts is given by the Poissonian ensemble average: \( \bar{\lambda}(\mathbf{r}) = \langle N_c(\mathbf{r}) \rangle \) and is directly related to the expected galaxy density \( \rho_d \) at that position: \( \rho_d(\mathbf{r}) = \langle N_c(\mathbf{r}) \rangle/\Delta V \). Here, \( \langle |\{\mathbf{s}\}\rangle \equiv \langle |\{\mathbf{s}\}| \rangle \equiv \sum_{N_c=0}^{\infty} P_{\text{Pois}}(N_c | \bar{\lambda}() \rangle \) denotes an ensemble average over the Poissonian distribution. We further model the observational selection of \( N_o(\mathbf{r}) \) galaxies out of the \( N_c \) present within the small volume \( \Delta V \) to be a binomial selection with an acceptance rate \( w(\mathbf{r}) \). We can then write

\[
N_o(\mathbf{r}) \sim P_{\text{Bin}}(N_o(\mathbf{r})|N_c(\mathbf{r}), w(\mathbf{r})),
\]

with

\[
P_{\text{Bin}}(N_o(\mathbf{r})|N_c(\mathbf{r}), w(\mathbf{r})) = \binom{N_c(\mathbf{r})}{w(\mathbf{r})} (1 - w(\mathbf{r}))^{N_c(\mathbf{r}) - w(\mathbf{r})}.
\]

The expected mean observed number of galaxies in the volume \( \Delta V \) is

\[
\langle N_o(\mathbf{r}) \rangle_w = w(\mathbf{r})N_c(\mathbf{r}),
\]

where \( \langle |\{\mathbf{s}\}\rangle_w \equiv \langle |\{\mathbf{s}\}| \rangle_{N_o, w} \equiv \sum_{N_o=0}^{\infty} P_{\text{Bin}}(N_o | N_c, w) \} \) represents the ensemble average over the binomial distribution with a selection probability \( w \). Consequently, one can model the observed number of galaxies, as a single Poissonian process:

\[
N_o(\mathbf{r}) \sim P_{\text{Bin}}(N_o(\mathbf{r})|\bar{\lambda}(\mathbf{r}))
\]

with mean

\[
\bar{\lambda}(\mathbf{r}) = w(\mathbf{r})\bar{\lambda}(\mathbf{r}) = w(\mathbf{r})(N_c(\mathbf{r}))_w = \langle N_o(\mathbf{r}) \rangle_w.
\]

Note that the Poissonian and the binomial distributions commute with each other.

### 3.2.3 Noise covariance and data autocorrelation matrix

Let us define the noise covariance matrix, according to the assumptions made in the previous section, as the shot noise resulting from an inhomogeneous Poisson distribution for the galaxy distribution \( n(\mathbf{s}) \) and a binomial distribution for describing the observation process which reduces the fraction of observed galaxies following the
selection function. We then obtain an expression for the noise covariance:

\[ N_{SD}(s_1, s_2) \equiv \langle e(s_1)e(s_2) \rangle_{(\delta_{\text{m}}, p_m)} \equiv \langle e(s_1)e(s_2) \rangle_w \]

\[ = \frac{1}{\pi} \left( \langle \langle n_r^n(s_1)n_r^n(s_2) \rangle_w \rangle_w - \langle n_r^n(s_1) \rangle_w \langle n_r^n(s_2) \rangle_w \right) \]

\[ = \frac{1}{\pi} \langle n_r^n(s_1) \delta_0(s_1 - s_2) \rangle_w \]

\[ = \frac{1}{\pi} \langle u(s_1) \delta_0(s_1 - s_2) \rangle_w \delta_0(s_1 - s_2), \] (20)

where we have used the properties of the variance and mean of these distribution functions and have added the superscript SD to denote that this covariance matrix is signal dependent (see Section 2.5.3 and appendix A in Kitaura & Enßlin 2008). Note that this noise covariance is defined as the ensemble average of the correlation matrix of the noise over all possible noise realizations denoted by the subscript \( e \) \( \delta_{\text{m}}, p_m \) with \( p_m \) being a set of parameters which determine the noise. Here, we have neglected the cell-to-cell correlation introduced by the gridding scheme we have used (TSP) as the first step in our supersampling scheme.

Having defined the data model, together with the noise model, we can calculate the expected data autocorrelation matrix, which is defined as the ensemble average over all possible galaxy realizations and density realizations (cosmic variance) leading to the following expression:

\[ \left\langle \left\langle s_g^{\text{th}}(s_1)\delta_r^{\text{th}}(s_2) \right\rangle_w \right\rangle_m \]

\[ = u(s_1)u(s_2) \int dr_1 Z(s_1, r_1) \int dr_2 Z(s_2, r_2) \]

\[ \times \int dr_1' B(r_1 - r_1') \int dr_2' B(r_2 - r_2') \delta_0(r_1')\delta_0(r_2') \]

\[ + \langle N(s_1, s_2) \rangle_m. \] (21)

with \( \langle \rangle_m \equiv \langle \rangle_{(\delta_{\text{m}}, p_m)} \equiv \int d\delta_\text{m} P(\delta_{\text{m}} | p_m) \) being the ensemble average over all possible matter density realizations with some prior distribution \( P(\delta_{\text{m}} | p_m) \) with \( p_m \) being a set of parameters which determine the matter field, say the cosmological parameters. Note that this equation is only valid in the approximation where the bias and the redshift distortion operators are linear.

The noise term in equation (21) has the following form:

\[ N_{LSQ}(s_1, s_2) \equiv \left\langle N_{SD}(s_1, s_2) \right\rangle_m \equiv \langle e(s_1)e(s_2) \rangle_{(\delta_{\text{m}}, e(p))} \]

\[ = \frac{1}{\pi} \langle u(s_1) \delta_0(s_1 - s_2) \rangle_w \] (22)

since \( \langle \langle n(r) \rangle_w \rangle_m = \langle \langle 1 + \delta r \rangle_w \rangle_m = \pi \), assuming again that the observed volume is a fair sample of the Universe. The noise covariance has been denoted with the superscript LSQ because it corresponds to the expression which is obtained by performing the LSQ approach to derive the WF, i.e. minimizing the ensemble average of the squared difference between the real underlying density field \( \delta_{\text{m}} \) and the LSQ estimator \( \delta_{\text{LSQ}} \) over all possible signal \( \delta_{\text{m}} \) and noise \( e \) realizations: \( \langle \delta_{\text{m}} - \delta_{\text{LSQ}} \rangle_{(\delta_{\text{m}}, e(p))} ) \) with \( p \) being the joint set of parameters: \( p \equiv \{ p_m, p_e \} \) (for a derivation, see appendix B in Kitaura & Enßlin 2008). We have also assumed that the cross-terms between the noise and the signal are negligible: \( \langle \delta_{\text{m}} e \rangle \rangle_m = 0 \). This should be further analysed in future work. Higher order correlations between the noise and signal in fact exist, and can be exploited using schemes such as the Poissonian scheme proposed in (Kitaura & Enßlin 2008). Note, however, that we consider a signal-dependent noise for the WF equation (20) which requires a model for the expected observed galaxy number density \( \langle n_i^n(s_i) \rangle_w \) (for differences in the derivation, see Kitaura & Enßlin 2008). We restrict ourselves to the LSQ noise covariance model \( N_{LSQ} \) given by equation (22) in our application to the SDSS data (Section 5).

Note that the LSQ representation of the WF is a linear operator in contrast to the alternative formulation which depends on the signal and thus is a non-linear filter. We explore methods to deal with the signal-dependent noise formulation with mock galaxy catalogues and compare the results to the LSQ version of the WF (see Section 4).

Note that by construction, the data autocorrelation matrices for the observed galaxy overdensity field and the theoretical overdensity field are identical given the noise model in equation (20):

\[ \left\langle \left\langle \langle s_g^{\text{th}}(s_1)\delta_r^{\text{th}}(s_2) \rangle_w \right\rangle_w \right\rangle_m = \left\langle \left\langle \langle \delta_r^{\text{th}}(s_1)\delta_r^{\text{th}}(s_2) \rangle_w \right\rangle_w \right\rangle_m. \] (23)

### 3.3 Reconstruction algorithm

In this section, we propose a two-step reconstruction process: first a WF step and second a deconvolution step.

#### 3.3.1 Wiener filtering

First, we recover the galaxy field in the redshift space \( (\delta_{g,z}) \) by applying the WF. The version of the WF we use can be derived as follows. Let us approximate the posterior distribution assuming a Gaussian prior and a Gaussian likelihood:

\[ P(\delta_{g,z} | \delta_{g,z}^0, p) \propto \exp \left( -\frac{1}{2} \langle \delta_{g,z} - \delta_{g,z}^0 \rangle_{(\delta_{\text{m}}, e(p))} \right) \]

\[ + \langle \delta_{g,z} - W_{g,z} \delta_{g,z} \rangle_{(\delta_{\text{m}}, e(p))} \right) \delta_{g,z}^0 \right) \]

\[ \right) \delta_{g,z} \right) \] (24)

with the signal autocorrelation matrix \( S_{g,z} \equiv \langle \delta_{g,z}(\delta_{g,z}) \rangle \) being the inverse Fourier transform of the assumed model galaxy power spectrum in the redshift space: \( \tilde{S}_{g,z}(k, k') \equiv (2\pi)^3 P_g(k) \delta_{g,z}(k - k') \) and the hats denoting the Fourier transform of the signal autocorrelation matrix. Note that the posterior distribution also depends on a set of parameters \( p \) which determine the power spectrum \( P_g(k) \).

The log-posterior distribution is then given by

\[ \log P(\delta_{g,z} | \delta_{g,z}^0, p) \propto \]

\[ \delta_{g,z} \quad S_{g,z}^{-1} \delta_{g,z} + \langle \delta_{g,z} - W_{g,z} \delta_{g,z} \rangle_{(\delta_{\text{m}}, e(p))} \rangle_{(\delta_{\text{m}}, e(p))} \]

\[ \delta_{g,z} + \langle \delta_{g,z} - W_{g,z} \delta_{g,z} \rangle_{(\delta_{\text{m}}, e(p))} \rangle_{(\delta_{\text{m}}, e(p))} \]

\[ - \delta_{g,z} \quad S_{g,z}^{-1} \delta_{g,z} \]

\[ \delta_{g,z} - \delta_{g,z} \quad S_{g,z}^{-1} \delta_{g,z} \]

\[ - \delta_{g,z} \quad S_{g,z}^{-1} \delta_{g,z} \]

\[ (25) \]

The first two terms can be combined to one term: \( \delta_{g,z} \quad (\sigma_{g,z}^{-1}) \quad \delta_{g,z} \) using the Wiener variance: \( \sigma_{g,z}^{-1} \equiv \langle S_{g,z}^{-1} \rangle \). To find the mean of the posterior distribution, we seek an expression for the log-posterior of the form

\[ \log P(\delta_{g,z} | \delta_{g,z}^0, p) \propto \delta_{g,z} \quad (\sigma_{g,z}^{-1}) \quad \delta_{g,z} \]

\[ \delta_{g,z} \quad (\sigma_{g,z}^{-1}) \quad \delta_{g,z} \]

\[ (26) \]

with \( \langle \delta_{g,z} \rangle_{WF} = \tilde{F}_{WF} \sigma_{g,z}^{-1} \) being the mean after applying the WF \( F_{WF} \) to the data. Now the third and the fourth terms of equation (25) can be identified with the terms in equation (26) as

\[ - \delta_{g,z} \quad S_{g,z}^{-1} \delta_{g,z} \]

\[ - \delta_{g,z} \quad (\sigma_{g,z}^{-1}) \quad F_{WF} \delta_{g,z} \]

\[ (27) \]
and

$$-\delta_{g,z}^i N^{-1} w_{g,z} \delta_g \equiv -\delta_{g,z}^i F_{WF} (\sigma_{WF}^{-1})^{\frac{1}{2}} \delta_{g,z}.$$ \hspace{1cm} (28)$$

respectively. The remaining term depends only on the data and is thus factorized in the posterior distribution function as part of the evidence. From both equations (27) and (28), we conclude that the WF has the form

$$F_{WF} = \sigma_{WF}^{-1} W_{g}^{-1} = (S^{-1} + W_{g}^{-1} \mu^{-1})^{-1} W_{g}^{-1} \mu.$$ \hspace{1cm} (29)$$

The mean \( \langle \delta_{g,z} \rangle_{WF} \) of the posterior distribution defined by equation (24) can be obtained by

$$\langle \delta_{g,z} \rangle_{WF} = (S^{-1} + W_{g}^{-1} \mu^{-1})^{-1} W_{g}^{-1} \mu.$$ \hspace{1cm} (30)$$

We favour this signal-space representation of the WF with respect to the equivalent and more frequently used data-space representation in LSS reconstructions: \( \langle \delta_{g,z} \rangle_{WF} = S^{-1} W_{g}^T (W_{g} S_{g}^{-1} + N)^{-1} \delta_{g,z} \) (see e.g. Zaroubi et al. 1995), because it avoids instabilities which otherwise arise in our rapid algorithm for evaluating the filter.

Let us distinguish between the linear LSQ and the non-linear signal-dependent noise formulation of the WF. The first takes the matter-field-averaged covariance equation (22) \( N = N^{LSQ} \) and is used below when analysing the SDSS data (see Section 5). In the case of a signal-dependent noise: \( N = N^{SD} \), one needs an estimate of the expected observed galaxy number density \( w(s) \lambda(s) \equiv \langle n(s) \rangle_{g} \) (see equation 20 and Section 3.4.2). Such an approach was done by Erdogdu et al. (2004).

### 3.3.2 Deconvolution step

In the second reconstruction step, we deconvolve the galaxy field \( \langle \delta_{g,z} \rangle_{WF} \) from the assumed redshift distortion and galaxy bias operators, obtaining an estimate for the underlying matter field in the real space:

$$\langle \delta_{m,z} \rangle_{WF} = B_{m}^{-1} Z_{m}^{-1} \langle \delta_{g,z} \rangle_{WF}.$$ \hspace{1cm} (31)$$

In this approximation, we can easily transform the reconstructed galaxy field into the matter field by just performing a final deconvolution with some scale-dependent bias of the form \( \hat{B}(k, k') \equiv b(k) \delta_b(k - k') \). As already mentioned above, our result should not be restricted to a single arbitrary chosen bias model. We therefore choose to recover the galaxy field by assuming a bias equal to unity from which matter reconstructions for all possible (and invertible) bias schemes can easily be constructed via equation (31). Note that an alternative representation of the WF which regularizes the bias and the redshift distortion operator when they are not invertible consists of including them in the response operator (equation 13) when calculating the WF, leading to \( \langle \delta_{m,z} \rangle_{WF} = (S_{m}^{-1} + R_{m}^{-1} \mu^{-1})^{-1} R_{m}^{-1} \mu^{-1} \delta_{g,z} \).

### 3.3.3 Redshift distortion operator

Following Erdogdu et al. (2004), we define the power spectrum in the redshift space as the product of the power spectrum in the real space and an effective redshift distortion factor given by the angle-averaged Kaiser factor \( K(k, \mu) \) times the damping Lorentzian factor \( D(k, \mu) \): \( P^\mu_{m}(k) \equiv \langle K(k, \mu) D(k, \mu) \rangle_{\mu} P_{m}(k) \).

$$P^\mu_{m}(k) \equiv \langle K(k, \mu) D(k, \mu) \rangle_{\mu} P_{m}(k).$$ \hspace{1cm} (32)$$

with \( \mu = k \cdot r / (|k| |r|) \). The Kaiser factor is given by (see Kaiser 1987)

$$K(k, \mu) \equiv (1 + \beta \mu^2)^2,$$ \hspace{1cm} (33)$$

with \( \beta \) being the redshift distortion parameter which can be approximated by \( \beta \approx \Omega_m^{0.4} \), assuming a constant bias equal to unity and neglecting dark energy dependences (see Lahav et al. 1991). The Lorentzian damping factor is based on an exponential distribution in the real space for the pairwise peculiar velocity field and is given by

$$D(k, \mu) \equiv \frac{1}{1 + (k^2 \sigma_z^2 \mu^2)^2}.$$ \hspace{1cm} (34)$$

with \( k \equiv |k| \) and \( \sigma_z \), being the average dispersion velocity of the galaxies, which we assume to be \( \sigma_z = 500 \, \text{km} \, \text{s}^{-1} \, H_0^{-1} \) (see e.g. Ballinger, Peacock & Heavens 1996; Jing, Mo & Boerner 1998; Jing & Börner 2004; Li et al. 2006a).

We refer to Erdogdu et al. (2004) for the angle-average expression of the product of the Kaiser factor and the damping factor. Consequently, we introduce the angular-averaged redshift distortion operator defined as the square root of the factor in the previous equations:

$$\tilde{Z}(k, k') \equiv \sqrt{(K(k', \mu) D(k', \mu) \rangle_{\mu} \delta_b(k - k')}.$$ \hspace{1cm} (35)$$

By construction, this operator yields the correct power-spectrum modification for the translation from real to the redshift space.\(^\dagger\)

Note that this approximation is valid up to second-order statistics and gives only an effective solution to the redshift distortion due to the angular averaging. A proper solution would require a phase and direction-dependent redshift distortion operator. If we assume that the galaxy bias is unity, we then can write the galaxy power spectrum in the redshift space as \( P_E^\mu(k') \equiv \langle K(k, \mu) D(k, \mu) \rangle_{\mu} P_{m}(k) \). Note that this reduces the validity of our reconstruction to scales larger than the mesh resolution which is of about 1 Mpc to scales of about 10 Mpc. The power spectrum in the real space \( P_{m}(k) \) is given by a non-linear power spectrum that also describes the effects of virialized structures with a halo term as given by (Smith et al. 2003) at redshift \( z = 0 \). In addition to the cosmological parameters presented in Section 3.1.1, we assume a spectral index \( n_s = 1 \).

With each of the required operators defined, we can now apply our reconstruction algorithm as we demonstrate in the next section.

### 3.4 Signal-dependent noise formulation of the Wiener filter

To apply the signal-dependent noise formulation of the WF, one needs to find estimators for the expected density field in the signal-dependent noise covariance (equation 20). We require a good estimator either for \( \lambda^0(r) \equiv \langle N^0(z) \rangle_{g} \) or for \( \lambda(r) \equiv \langle N_c(r) \rangle_{g} \) since \( \lambda^0(r) \equiv \langle w(r) \lambda(r) \rangle_{g} \).

\(^\dagger\) Note that we deviate here from Erdogdu et al. (2004) in the order of the angular averaging and square root. An inspection of the power spectrum corresponding to the reconstructions however shows that only the prescription as implemented here leads to agreement with the non-linear (Smith et al. 2003) power spectrum.
frequentist approach by assuming a flat prior for the overdensity distribution or equivalently infinite cosmic variance.

Let us start with the Bayes theorem:

$$ P(\lambda^0|N^0_c) = \frac{P(N^0_c|\lambda^0)\, P(\lambda^0)}{P(N^0_c)}. $$

(36)

The flat prior is defined as $P(\lambda^0) = c$, with $c$ being a constant. The evidence is then given by

$$ P(N^0_c) = \int_0^\infty d\lambda^0 \, P(N^0_c|\lambda^0) \, c = c,$$

(37)

since

$$ \int_0^\infty d\lambda^0 \, P(N^0_c|\lambda^0) = \int_0^\infty d\lambda^0 \, \frac{(\lambda^0)^{N^0_c} e^{-\lambda^0}}{N^0_c!} = \Gamma(N^0_c + 1) \, N^0_c! = 1.$$  

(38)

Consequently, we obtain that the posterior distribution is equal to the likelihood

$$ P(\lambda^0|N^0_c) = P(N^0_c|\lambda^0).$$

(39)

The maximum likelihood estimator $\lambda_{\text{max}}$ is obtained by looking at the extrema:

$$ 0 = \frac{\partial P(\lambda_{\text{max}}|N^0_c)}{\partial \lambda_{\text{max}}} $$

$$ = (N^0_c w_{\lambda_{\text{max}}})^{-1} \, w - w_{\lambda_{\text{max}}} \frac{w_{\lambda_{\text{max}}}^{N^0_c} e^{-w_{\lambda_{\text{max}}}}}{N^0_c!} $$

$$ = N^0_c \lambda_{\text{max}}^{-1} \, w, $$

(40)

leading to

$$ \lambda_{\text{max}} = \frac{N^0_c}{w}. $$

(41)

Note that the maximum estimator $\lambda_{\text{max}}$ is not a valid estimator for the noise covariance matrix, since it can become zero at cells in which no galaxy count is present even if the cell belongs to the observed region. The mean estimator $\lambda_{\text{mean}}$ can be found by performing the following integral:

$$ \lambda_{\text{mean}} = \int_0^\infty d\lambda^0 \, \lambda^0 \, P(\lambda^0|N^0_c) $$

$$ = \int_0^\infty d\lambda^0 \, \frac{(\lambda^0)^{N^0_c+1} e^{-\lambda^0}}{(N^0_c+1)!} \, (N^0_c + 1). $$

(42)

Thus, we have

$$ \lambda_{\text{mean}} \equiv \frac{\lambda_{\text{mean}}}{w} = \frac{1}{w} \, (N^0_c + 1). $$

(43)

The mean estimator $\lambda_{\text{mean}}$ gives a regularized solution with respect to the maximum estimator $\lambda_{\text{max}}$ overcoming the problem of having zero noise at cells with zero observed number counts. Both estimators however rely on the flat prior assumption which can be dominated by the shot noise for low completeness. This can be a problem when the reconstruction is performed on a fine mesh with extremely low completeness. For this reason, we test the SD WF with an alternative scheme presented in the next section.

### 3.4.2 Statistically unbiased jackknife-like scheme

The jackknife-like scheme we present here and test in the next section produces subsamples from a galaxy distribution with selection function effects which are statistically unbiased with the underlying mean number density having a noise term with a structure function depending only on $\lambda(r)$. The first step of the scheme consists of generating a subsample using the binomial distribution given the observed number counts and the selection probability $\alpha/w(r)$ with a tunable parameter $\alpha < \text{min}(w(r))$:

$$ N'_c(r) \sim \left\{ \begin{array}{ll}
P_{\text{bin}}(N_c(r) \mid N'_c(r), \frac{\alpha}{w(r)}) \\
P_{\text{poi}}(N'_c(r) \mid \alpha \lambda(r))
\end{array} \right\}.$$  

(44)

One can note that the ensemble average over all possible $\alpha$ realizations leads to the mean number density $\lambda(r)$:

$$ \langle \langle N'_c(r) \rangle \rangle_{\alpha} = \frac{1}{\alpha} \langle \langle N'_c(r) \rangle \rangle_{\alpha} = \langle \langle N_c(r) \rangle \rangle_{\alpha} = \lambda(r). $$

(45)

Here, $\{ \langle \rangle \}_{\alpha}$ is a binomial average with acceptance frequency $\alpha$. The estimator for $(\lambda(r))_{\alpha} \equiv \langle w(r) N'_c(r) \rangle_{\alpha}$, with the subscript JK standing for the jackknife estimator. We test the estimator proposed here to sample the noise covariance (see Section 4).

### 4 QUALITY VALIDATION OF THE RADIAL SELECTION FUNCTION TREATMENT

In this section, we evaluate the quality of the reconstruction method under several incompleteness conditions. We restrict the study to a mesh of 128$^3$ cells for a cube with 500 Mpc side length and ignore bias and redshift distortion effects. The necessity of performing a reconstruction step to make further studies of the LSS is addressed. More simple schemes in which the galaxies are just gridded and the resulting field smoothed are shown to lead to significantly worse estimates of the matter field.

For this study, we consider a homogeneous subsample of 10$^6$ galaxies in a 500 Mpc cube box from the mock galaxy catalogue by (De Lucia & Blaizot 2007) selected at random based on the Millennium Simulation (Springel et al. 2005). We define the 10$^6$ galaxy sample as our complete sample. Then, we generate two incomplete samples by radially selecting the galaxies according to two different radial completeness functions $w_{\text{MOCK1}}$ and $w_{\text{MOCK2}}$, respectively (see Fig. 1). This is done by drawing random uniform numbers between 0 and 1 for each mock galaxy and selecting the galaxies depending on whether the drawn number is above or below the value of the completeness at the corresponding distance to the observer. Note that this ensures a perfect binomial observation process treating all the galaxies independent of their luminosity and thus avoiding the problem of galaxy biasing. The observer is defined in both cases at an equivalent position in the box to the real observer in the application to the observed DR6 data (Section 5), namely at $X = 0$ Mpc, $Y = 250$ Mpc and $Z = 20$ Mpc. Note that the arbitrary coordinates of the mock data range from 0 to 500 Mpc in each direction $X$, $Y$ and $Z$.

We consider the LSQ formulation of the WF, which is a linear filter with a homogeneous noise term multiplied with a structure function given by the selection function equation (22), and the signal-dependent noise formulation, which is a non-linear filter as it depends on the signal (see equation 20), and the 1W scheme. In addition to the Wiener-reconstruction methods, we define an 1W scheme to estimate the underlying matter field as follows: first each galaxy is weighted with the inverse of the completeness at its location, then the galaxy sample is gridded according to the corresponding particle masses (we use our supersampling scheme to suppress aliasing) and finally the resulting field is convolved with
different smoothing kernels. The first part of this scheme, leaving the smoothing for a later step, can be summarized by the following equation:

\[
\langle n(r) \rangle_{\text{IW}} = \frac{1}{V} \int dV K_s(r - r') \frac{1}{w(r')} n_o(r'),
\]  

where we have denoted the corresponding estimator by the angles: \(\langle \{ \} \rangle_{\text{IW}}\). Note that the completeness cannot be zero at a position in which a galaxy was observed. In order to make a quantitative comparison between the two Wiener-filtering methods and the IW method, a true underlying field \(\delta_{\text{true}}\) needs to be defined. Since the IW scheme does not correct for the shot noise, we will compare with the complete mock galaxy sample (see panel c in Fig. 2) after smoothing on different scales. Note that a consistent comparison for this case is difficult, since the shot noise varies with the different galaxy samples and with the distance to the observer. For the Wiener reconstruction case study, we define the true underlying matter field \(\delta_{\text{true}}\) as the resulting Wiener reconstruction taking the complete mock galaxy sample (see panel e in Fig. 2). Note that the true field thus also differs between our two Wiener-filtering schemes. We will denote the reconstructed fields with each method as \(\delta_{\text{rec}}\).

### 4.1 Statistical correlation measures

To give a quantitative measurement of the quality of the reconstructions, we define the correlation coefficient \(r\) between the reconstructed and the true density field by\(^{11}\)

\[
 r(\delta_{\text{rec}}, \delta_{\text{true}}) = \frac{\sum_i N_{\text{cells}} \delta_{i}^{\text{true}} \delta_{i}^{\text{rec}}}{\sqrt{\sum_i N_{\text{cells}} (\delta_{i}^{\text{true}})^2} \sqrt{\sum_i N_{\text{cells}} (\delta_{i}^{\text{rec}})^2}}.
\]  

\(^{11}\) Not to be confused with the comoving distance \(r\).
The cell-to-cell plot of the reconstruction against the true density field is highly informative because the scatter in the alignment of the cells around the line of perfect correlation (45° slope) gives a qualitative goodness of the reconstruction. In general, the quality of the recovered density map is better represented by the Euclidean distance between the true and the reconstructed signals (see Kitaura & Enßlin 2008). The ensemble average of this quantity over all possible density realizations can also be regarded as an action or a loss function that leads to the WF through minimization (see Kitaura & Enßlin 2008). Here, we introduce the Euclidean distance:

\[ D_{\text{Euc}}(\delta_{\text{rec}}, \delta_{\text{true}}) = \sqrt{\frac{1}{N_{\text{cells}}} \sum_{i} N_{\text{cells}} \left( \delta_{i,\text{rec}} - \delta_{i,\text{true}} \right)^2}, \tag{48} \]

with \( N_{\text{cells}} = 128^3 \) for the mock tests. Let us, in addition, define the normalized Kullback–Leibler distance \(^{12}\) (see Kullback & Leibler 1951) as

\[ D_{\text{KL}}(1 + \delta_{\text{rec}}, 1 + \delta_{\text{true}}) = \frac{1}{N_{\text{cells}}} \sum_{i} \left( 1 + \delta_{i,\text{rec}} \right) \log \left( \frac{1 + \delta_{i,\text{rec}}}{1 + \delta_{i,\text{true}}} \right). \tag{49} \]

In our analysis, we also compute smoothed versions of the density field convolving it with a Gaussian kernel given by

\[ G(r, r_{S}) = \exp \left( -\frac{|r|^2}{2r_{S}^2} \right), \tag{50} \]

with \( r_{S} \) being the smoothing radius.

4.2 First mock test

In the first mock test, we try to emulate the same completeness conditions as given in the observed DR6 sample. For that, we take the complete mock galaxy catalogue \((10^6\) galaxies\) and select according to the DR6 radial selection function \(w_{\text{DR6}}(r)\) a subsample leaving about 20 per cent of the total number of galaxies \((218\ 020)\) (see Fig. 2). The DR6 radial selection function can be seen as the black line in Fig. 1. A section through the box showing the completeness can be also seen in panel (b) of Fig. 2. The observer can be identified as being at the centre of the spherical shells with equal completeness. The resulting overdensity field after applying this selection function to the complete mock sample can be seen in panel (a) of Fig. 2. Note that we show here the mock-observed galaxy field by setting \( w = 1 \) in equation (6) in order to clearly see the selection effects. In the following, the discrete galaxy field (including Poisson noise) is represented with red colour and the noise-corrected field is represented in blue colour. We will define the complete mock galaxy field including Poisson noise (panel c in Fig. 2) as the true galaxy density field for the IW scheme. The corresponding noise-corrected fields using the LSQ WF (panel a in Fig. 3) and the SD WF (panel b in Fig. 3) are defined as the true galaxy density field for the Wiener reconstructions. The true dark matter field is approximately related to this via equation (9); however, here we want to exclude the complication of galaxy biasing.

Panel (d) in Fig. 2 shows the result after applying the IW scheme. Panels (b) and (d) of Fig. 3 show the respective reconstructions using the LSQ and the SD WF, respectively. One can clearly see the noisy reconstruction produced by the IW scheme for structures located at large distances to the observer in contrast to the smoother estimation made by the Wiener-filtering schemes. The SD WF was applied for the complete galaxy sample using our statistically unbiased jackknife-like scheme with an \( \alpha \) parameter of \( 10^{-3} \). The means after 200 reconstructions are shown in panels (c) and (d) for the complete and the selected samples, respectively. The corresponding statistical analysis can be seen in Fig. 4. The cell-to-cell correlation plots show the tendency of the IW scheme to overestimate the density while the opposite is true in a significantly more moderate way when applying the WF. In the case without smoothing (a mesh of size \( \sim 3.9 \) Mpc) (panels a and d in Fig. 4), the qualitative and quantitative difference between the methods is very large, showing a significantly better correlation coefficient and lower Euclidean and Kullback–Leibler distances for the Wiener reconstructions than for the IW scheme. Only when the fields are smoothed with a Gaussian of radius \( r_{S} = 5 \) Mpc does the difference between the matter field estimators drop. With this smoothing, the statistical correlation coefficient is similar for the WF and the IW scheme. However, the Euclidean and Kullback–Leibler distances remain being lower for the WF reconstructions (see Fig. 4).

4.3 Second mock test

For the second mock test results, we modify the DR6 selection function to drop faster towards larger radii leaving less than 10 per cent of the galaxies \((87\ 220)\) by weighting \( w_{\text{DR6}}(r)\) with the factor \( 100\ 000\ Mpc/r \) for \( r \geq 100 \) Mpc. The corresponding radial selection function \( w_{\text{MOCK2}}(r)\) can be seen as the dashed line in Fig. 1. The dramatic difference from DR6 completeness can be seen using LSQ and SD formulations, respectively. The noisy reconstruction produced by the IW scheme for structures located at large distances to the observer is now even more visible than in the previous test. Cells far away from the observed are excessively weighted. The WF in contrast gives a smoother and more conservative estimation in regions in which the data are more incomplete. However, it remains sharp in regions where the information content is high (see structures close to the observer).

The corresponding statistical analysis can be seen in Fig. 5. The tendency to overestimate the density of the IW scheme is now extreme. Smoothing helps to raise the correlation coefficient values and to decrease the Euclidean and Kullback–Leibler distances. They remain, however, clearly above the ones achieved with the WF schemes.

5 MATTER FIELD RECONSTRUCTIONS OF THE SDSS DR6

This work presents the first application of the \texttt{ARGO} code to observational data. This yields the matter field reconstruction of the SDSS DR6 in the main area of the survey which is located in the northern Galactic cap on a comoving cube of side 500 Mpc and \( 512^3 \) cells.

In this section we describe a few remarkable features in the reconstructed matter field, demonstrating the quality of the reconstruction and the scientific potential for future applications. First, we discuss the mask and the projected three-dimensional reconstruction without smoothing and after smoothing with a Gaussian kernel with smoothing radii of \( r_{S} = 5 \) Mpc and \( r_{S} = 10 \) Mpc as displayed in Fig. 6. We then describe the largest structures in the nearby Universe, in particular the Sloan and CfA2 Great Walls (see Geller & Huchra 1989; Gott et al. 2005). Later, we analyse void or cluster detections which can be made with this kind of work. Finally, we analyse the statistical distribution of matter.

\(^{12}\) Also called relative entropy in information theory.
Cosmic cartography of the LSS with SDSS DR6

5.1 Mask and completeness

The sky mask for the region is shown in panel (a) of Fig. 6. The high resolution (36 arcsec in both $\alpha$ and $\delta$) permits us to visualize the plates of the SDSS with the intersection of several plates leading to higher completeness. The mask is divided into three patches: one small beam at high declination and right ascension angles and two wide regions. All the patches together cover almost a quarter of the sky. Between the two wider regions, there is a large gap and there are several additional smaller gaps inside the patches. Such a complex mask is an interesting problem for the ARGO code. It allows us to test whether it can properly handle unobserved regions with zero completeness. Slices of the three-dimensional mask calculated as the product of the completeness on the sky and the selection function (see Section 3.1.3) are presented in panel (a) of Figs 8–10 and panel (e) of Fig. 9. In these plots, one can see how the selection function leads to a decrease of the completeness in the radial direction. Note that the observer is located at $(0, 0, 0)$ in our Cartesian coordinate system. We can see in panel (a) of Fig. 8 that the completeness rapidly reaches its maximum at around 110 Mpc distance from the observer and decreases at larger radii to values below 10 per cent. In the next section we show how remarkably homogeneous structures are recovered in our reconstruction, independent of the distance from the observer and despite the low completeness values at large distances. We confirmed with additional reconstructions with larger volumes the same behaviour for boxes up to side lengths of around 750 Mpc. For even larger volumes of a 1 Gpc size, not shown here, however, the main sample becomes too sparse and only the LSS are recovered. Including the three-dimensional completeness for the SDSS DR6 data (see Section 3.1.3) in equation (7), we obtain a mean galaxy density of about 0.05.
5.2 Mapping the Sloan and the CfA2 Great Wall

The Sloan Great Wall is one of the largest structures known in our local Universe although it is not a gravitationally bound object (see Gott et al. 2005). It extends for about $13 \times 400$ Mpc (for a detailed study, see Deng et al. 2006) and is located around 300 Mpc distant from Earth. In Fig. 7 we represent different radial shells, picking out the structures of the Sloan Great Wall, which extends from about $140^\circ$ to $210^\circ$ ($-150^\circ$ in Fig. 6) in right ascension and extends within a few degrees around declination $\delta \approx 0^\circ$. In these shells other complex structures can be observed at higher declinations, showing filaments, voids and clusters of galaxies. Moreover, the region which has not been observed, lying outside the mask (see panel a in Fig. 6), is predicted to be filled with structures by the reconstruction.
method according to our assumed correlation function (see Section 3.3.3). The Sloan Great Wall can also be seen in Fig. 8 almost in its full extent. We can see how ARGO recovers the matter field, balancing the structures with a low signal-to-noise ratio against those with a higher signal, leading to a homogeneously distributed field, meaning that clusters close to and far from the observer are both well represented. Only where the signal-to-noise ratio drops below unity do structures tend to blur, as can be observed in the upper parts of the reconstruction shown in Fig. 9.

The CfA2 Great Wall is also one of the largest structures known in our local Universe and contains the Coma Cluster (Abell 1656) at its centre (see Geller & Huchra 1989). We can clearly see the Coma Cluster in the projected reconstruction without smoothing, being the big spot at right ascension $\alpha \approx 195^\circ$ ($-165^\circ$ in Fig. 6) and declination $\delta \approx 28^\circ$ in panel (b) of Fig. 6, located at a distance of $\sim 100$ Mpc from the observer (see Thomsen et al. 1997; Carter et al. 2008). The CfA2 Great Wall cannot be seen in its full extent in Fig. 8 because it reaches higher declination angles than selected in the plot. However, it can be partially seen as an elongated matter structure at about a $100$ Mpc distance to the observer, i.e. at around $-100$ Mpc in the X-axis in Fig. 8. Large filamentary structures are present even after smoothing with a Gaussian kernel with a smoothing radius of $r_S = 10$ Mpc (see panel d in Fig. 8). The second major cluster of the Coma super-cluster is the Leo Cluster (Abell 1367) at a distance of $\sim 94$ Mpc ($z \approx 0.022$), with galactic coordinates $\alpha \approx 176^\circ$ and $\delta \approx 20^\circ$. It is weakly detected in our reconstruction as can be seen.
Figure 7. Different radial slices around the Sloan Great Wall. Shown are projections of the three-dimensional matter field reconstruction on the sky considering only cells with a comoving distance between 290 Mpc and 310 Mpc (panel a), 300 Mpc and 320 Mpc (panel b), 310 Mpc and 330 Mpc (panel c), and 320 Mpc and 340 Mpc (panel d). Note that the longitude angles $-90^\circ$, $-120^\circ$, $-150^\circ$ and $-180^\circ$ correspond to $270^\circ$, $240^\circ$, $210^\circ$ and $180^\circ$ right ascension angles, respectively, with the positive angles being equal. For a general right ascension angle $\alpha$, the longitude is calculated as $\alpha - 360^\circ$ for $\alpha \geq 180^\circ$. The latitude angles are identical to the declination angles.

in panel (b) of Fig. 6, since it is partially located in the major gap of DR6 and should be therefore better detected with DR7.

The Hercules supercluster also belongs to the CfA2 Great Wall. Most of the clusters which belong to this supercluster can be identified in the reconstructed area. Since the spatial range of these clusters is large, we have listed in Table 1 the groups of clusters with their respective localization in the sky which appear as especially prominent overdensity regions in the projected reconstruction (for references, see Abell, Corwin & Olowin 1989; Struble & Rood 1999). Note that close-by structures such as the Virgo Cluster, which is at a distance of only about 18 Mpc to us, cannot be detected in our reconstruction, because the lower limit of our sample is set at $z = 0.01$.

5.3 Detection of a great void region

The scorpion-like form of the matter distribution spanning the whole observed region in Fig. 9 (see the mask in panel a) shows large connected filamentary structures with many clusters. Interestingly, an extremely large void is spanned in the region with $-150 \text{ Mpc} < Y < 30 \text{ Mpc}$ and $70 < Z < 220 \text{ Mpc}$ (see panels a–c in Fig. 9). In order to evaluate the confidence of the detection, one should check how deeply this region has been scanned by the SDSS. By inspection of the three-dimensional mask, we confirm a fairly high completeness ranging from about 30 per cent to about 65 per cent (see panel a of Fig. 9). The extension in the $X$-axis is still unclear, since the gap in the mask grows in the void region to larger
Figure 8. Slices around the Sloan and the CfA2 Great Wall. Panel (a): slice through the three-dimensional mask multiplied with the selection function at \( \sim 7 \) Mpc in the \( Z \)-axis. Panels (b)–(d) show slices through the reconstruction after taking the mean over 20 neighbouring slices around the slice at \( \sim 7 \) Mpc in the \( Z \)-axis, without smoothing, convolved with a Gaussian kernel with a smoothing radius of \( r_S = 5 \) Mpc and \( r_S = 10 \) Mpc, respectively. Note that panel (b) represents \( \log(1 + \delta) \), whereas panels (c) and (d) show \( \delta \).

5.4 Cluster prediction

The signal-space representation of the WF (see Section 3.3.1) enables us to deal with unobserved regions, i.e. cells with zero completeness. Note that for these cells, the noise term vanishes in the WF expression (equation 30). The filter can then be regarded as a convolution with the non-diagonal autocorrelation matrix of the underlying signal propagating the information from the windowed region into the unobserved cells. This gives a prediction for the LSS in these regions. Such an extrapolation can be clearly seen in panels (b)–(d) of Fig. 6. These show the projected three-dimensional reconstruction on the sky without smoothing and after a convolution with a Gaussian with smoothing radii \( r_S \) of 5 and 10 Mpc, respectively. In these plots the gaps are hardly distinguishable, due to the signal prediction given by the WF. We have chosen a slice, in which the propagation of the information through gaps can be analysed. In panel (a) of Fig. 10, we can see the three-dimensional mask through our selected slice. The main gap crosses the entire box through the \( Y \)-axis and reaches about 50 Mpc width in the \( Z \)-axis. Several other smaller gaps are distributed in the slice. In the reconstruction in panel (b), we can see how the main gap is partially filled with some diffuse overdensity structures which are produced precisely as described above. Panel (c) shows the same reconstruction smoothed with a Gaussian kernel with a smoothing radius of \( r_S = 5 \) Mpc. The mask showing the regions in which it was observed is overplotted.
Figure 9. Panel (a): slice through the three-dimensional mask multiplied with the selection function at $\sim -109$ Mpc in the X-axis. Panels (b)–(d) show slices through the reconstruction after taking the mean over 20 neighbouring slices around the slice at $\sim -109$ Mpc in the X-axis, without smoothing, convolved with a Gaussian kernel with a smoothing radius of $r_S = 5$ Mpc and $r_S = 10$ Mpc, respectively. Panel (e): slice through the three-dimensional mask multiplied with the selection function at $\sim -168$ Mpc in the X-axis. Panel (f) shows a slice through the reconstruction after taking the mean over 20 neighbouring slices around the slice at $\sim -168$ Mpc in the X-axis without smoothing. Note that panels (b) and (f) represent $\log(1 + \delta)$, whereas panels (c) and (d) show $\delta$.

Figure 10. Panel (a): slice through the three-dimensional mask multiplied with the selection function at $\sim −256$ Mpc in the X-axis. Panels (b) and (c) show slices through the reconstruction after taking the mean over 20 neighbouring slices around the slice at $\sim −256$ Mpc in the X-axis, without smoothing and convolved with a Gaussian kernel with a smoothing radius of $r_S = 5$ Mpc, respectively. Panel (d): DR7 sample gridded with NGP and convolved with a Gaussian kernel with a smoothing radius of $r_S = 5$ Mpc. In panels (c) and (d), the DR6 mask is overplotted. Note that there is some correspondence between the structures predicted in the gap from the Sample dr6fix and the observed galaxy distribution there in DR7. Note that panel (b) represents $\log (1 + \delta)$, whereas panels (c) and (d) show $\delta$. 

© 2009 The Authors. Journal compilation © 2009 RAS, MNRAS 400, 183–203
We identify seven clusters close to gaps extending into unobserved regions at a slice around $-265 < X < -245$ Mpc (see clusters c$_1$–c$_7$ in Table 2). In addition, there are some weaker detections (see clusters c$_8$–c$_{10}$ in Table 2). The gap which cluster c$_1$ extends into and the largest gap are the ones in which more information propagation occurs. There is an especially interesting region in the main gap around $-140 < Y < 30$ Mpc in which the algorithm predicts a high chance to find overdense structures. The rest of the gaps remains with low density values, since no prominent structures are in their vicinity. We investigate the public DR7 archive (see Section 2) to check for overdense regions in the gap. Note that without a full angular and radial selection function treatment, a quantitative comparison is not possible. We restrict our study by gridding the galaxy sample with the NGP, ignoring mask or selection function effects and convolving it with a Gaussian kernel with a smoothing radius of $r_S = 10$ Mpc (see panel d in Fig. 10). Though faint features such as the filaments lying at around $-230 < Y < -130$ Mpc cannot be recovered, stronger features such as the clusters located at $-100 < Y < 0$ Mpc show that there is indeed an overdense region in the gap confirming our prediction based on DR6. In particular, the extension of the clusters c$_1$ and c$_2$ are very well predicted by our algorithm. Cluster c$_3$ is weakly predicted. The filament connecting clusters c$_1$ and c$_2$ is predicted by ARGO, perhaps by chance, but the resemblance in the gap of the reconstruction to the real underlying distribution shows that use of the correlation function of the LSS allows for plausible predictions.

5.5 Statistics of the density field

From a physical point of view, one would expect a lognormal distribution of smoothed density for a certain range of smoothing scales, if one assumes an initial Gaussian velocity field and extrapolates the continuity equation for the matter flow into the non-linear regime with linear velocity fluctuations (see Coles & Jones 1991). Since the lognormal field is not able to describe caustics, we expect this distribution to fail below a threshold smoothing scale. There should also be a transition at a certain scale between this quasi-linear regime and the linear regime where the matter field is still Gaussian distributed. Due to use of the WF which considers only the correlation function to reconstruct the density field and the Gaussian smoothing, we expect the density field to be closely Gaussian distributed in the unobserved regions. Here, we analyse the statistical distribution of the density field by counting the number of cells at different densities with a density binning of 0.03 in $(1 + \delta_m)$ at different scales, defined by convolving the reconstruction with a Gaussian kernel with smoothing radii $r_S$ of 10, 20 and 30 Mpc. We performed the analysis for different radial shells in the $\Delta r^{14}$ ranges: $0 < r < 200$ Mpc, $200 < r < 400$ Mpc, $r > 400$ Mpc and $0 < r < 600$ Mpc, separating observed ($w > 0$) and unobserved ($w = 0$) regions (see Figs 11 and 12). Note that due to shot noise, we are missing power in the filtered reconstruction on small scales. Moreover, the discrete Fourier representation of the signal implies negative densities (see Jasche et al. 2009). This obliges us to perform this statistical analysis on scales larger than the smallest grid scales. We can see this in the excess of low density cells for the dashed black curve ($r_S = 5$ Mpc). In addition to that, we are also limited by the size of the box, having less information as we go to larger and larger scales. This effect can be appreciated in the stronger deviation from the lognormal fit around the peak for the green line ($r_S = 30$ Mpc). For this reason, we restrict this analysis to the range of scales given above. The plots in Figs 11 and 12 show how the distribution tends towards Gaussianity as we go to larger and larger scales.

We calculated the skewness and kurtosis to quantify the deviation from Gaussianity. Let us define here the statistical quantities required for our analysis. The number of cells contained in a shell of radial range $\Delta r$ is given by the sum of the number counts in each density bin $f_B^{\Delta r}$:

$$N_B^{\Delta r} \equiv \sum_i f_B^{\Delta r,i}.$$  (51)

The mean overdensity in $\Delta r$, which is very close to zero, is calculated as

$$\delta_B^{\Delta r} = \frac{1}{N_B^{\Delta r}} \sum_i f_B^{\Delta r,i} \delta_B^{\Delta r,i}.$$  (52)

with the superscript $B$ standing for bin. These two previously defined quantities permitted us to calculate the central $n$-moments $\mu_n$ of the distribution with

$$\mu_n(\Delta r) \equiv \frac{1}{N_B^{\Delta r}} \sum_i f_B^{\Delta r,i} (\delta_B^{\Delta r,i} - \delta_B^{\Delta r})^n.$$  (53)

Note that the variance is just the second moment: $\sigma^2 = \mu_2$. Now, we can define the skewness:

$$s \equiv \frac{\mu_3}{\sigma^3}$$  (54)

and the kurtosis:

$$k \equiv \frac{\mu_4}{\sigma^4} - 3.$$  (55)

Let us also introduce Pearson’s skewness defined as the mean $\delta_B$ minus the mode $\delta_B^{\text{max}}$ (overdensity bin with the maximum number of counts max $(f)$) normalized by the square root of the variance:

$$s_p(\Delta r) \equiv \frac{\delta_B - \delta_B^{\text{max}}}{\sigma(\Delta r)}.$$  (56)

The results are shown in Figs 11 and 12 demonstrating large deviations from Gaussianity in the observed regions and negligible deviations for the unobserved regions. Since the WF uses only the first two moments of the matter distribution, we do not expect large deviations from Gaussianity in the unobserved regions where there are almost no data constraining the result. Note that in Figs 11 and 12, the skewness and kurtosis are also given (skewness: $s_{10}$, $k_{10}$).
Figure 11. Statistical distribution of cells at different densities with a density binning of 0.03 in \((1 + \delta_m)\). The curves represent the distribution for the reconstructed matter field at different scales \((r_S):\) continuous: 10 Mpc, dashed: 20 Mpc, dotted: 30 Mpc. The upper panels show the statistics at different radial shells in the observed region \((w > 0)\) and the lower panels show the same in the unobserved region \((w = 0)\). The corresponding skewness: \(s_{10}, s_{20}, s_{30}\); kurtosis: \(k_{10}, k_{20}, k_{30}\); and Pearson’s skewness: \(s_{P10}, s_{P20}, s_{P30}\) are also given.

Figure 12. Statistical distribution of cells at different densities with a density binning of 0.03 in \((1 + \delta_m)\). The dashed curves represent the distribution for the reconstructed matter field at different scales \((r_S):\) black: 10 Mpc, red: 20 Mpc, green: 30 Mpc. The corresponding skewness: \(s_{10}, s_{20}, s_{30}\); kurtosis: \(k_{10}, k_{20}, k_{30}\); and Pearson’s skewness: \(s_{P10}, s_{P20}, s_{P30}\) are also given. Left: (observed region: \(w > 0\)) continuous lines: best-fitting lognormal distributions using a non-linear least-squares fit based on a gradient-expansion algorithm, dashed–dotted curves: Gaussian distributions for the measured means and variances. Right: (unobserved region: \(w = 0\)), continuous lines: Gaussian distributions for the measured means and variances with the corresponding statistical correlation coefficients \(r_{20}, r_{40}\) and \(r_{60}\).
using a non-linear least-squares fit based on a gradient-expansion algorithm. For that, we parametrized the lognormal distribution as

\[ P(\delta|p) = \frac{a}{\log(1+\delta_m)} \exp\left[ b (\log(1+\delta_m) - c)^2 \right], \tag{57} \]

with \( p = [a, b, c] \) being a set of parameters. The results of the best fits normalized with the number of cells are shown as the continuous lines on the left-hand panel in Fig. 12. One can appreciate in all curves for \( \omega > 0 \) small tails towards low densities and long tails towards high densities showing a clear deviation from Gaussianity. The measured distributions are well fitted by the lognormal distribution of smoothed density for smoothing radii \( r_s \) of 10, 20 and 30 Mpc. We also calculated the mean and the variance and plotted the corresponding Gaussian distributions with light dashed-dotted lines. We therefore conclude that the distribution of the matter field is in good agreement with the lognormal distribution at least in the scale range of about \( 10 \lesssim r_s \lesssim 30 \) Mpc. This result is especially strong, since we did not assume a lognormal prior distribution in the reconstruction method. From a frequentist approach, the WF just gives the least-squares estimator without imposing any statistical distribution on the matter distribution. The picture from a Bayesian perspective is more precise: a Gaussian prior distribution for the underlying density field is assumed. The posterior distribution, however, is conditioned on the data, which finally imposes its statistical behaviour on to the reconstruction, as can be seen in our results.

6 CONCLUSIONS

We have presented the first application of the \textsc{arg} computer code to observational data. In particular, we have performed a reconstruction of the density field based on data from \textit{Sample dr6fix} of the NYU-VAGC (see Section 2). This yielded the largest Wiener reconstruction of the LSS made to date requiring the effective inversion of a matrix with about \( 10^9 \times 10^6 \) entries. The use of optimized iterative inversion schemes within an operator formalism (see Kitaura & Enßlin 2008), together with a careful treatment of aliasing effects (see Jasche et al. 2009), permitted us to recover the field on an Mpc mesh with an effective resolution of the order of \( \sim 10 \) Mpc. Furthermore, we have investigated in detail the statistical problem, in particular the noise covariance employed for performing Wiener reconstructions.

We have demonstrated that Wiener filtering leads to different results from those obtained by the commonly used method of inverse weighting the galaxies with the selection function. Both methods are comparable when the galaxy number counts per cell is high. However, in regions with sparse observed galaxy densities inverse weighting delivers very noisy reconstructions. This finding could have important consequences in power-spectrum estimation and galaxy biasing estimation on large scales.

As part of the results the Sloan Great Wall has been presented in detail (see Section 5.2) and some other prominent structures, such as the Coma, the Leo and the Hercules Cluster, have been discussed, as well as the detection of a large void region (see Section 5.3). Our results also show the detection of overdensity regions close to edges of the mask and predictions for structures in within gaps in the mask which compare well with the DR7 data in which the gaps are filled (see Section 5.4). Finally, we have analysed the statistical distribution of the density field finding a good agreement with the lognormal distribution for Gaussian smoothing with radii in the range \( 10 \lesssim r_s \lesssim 30 \) Mpc. We hope that this work highlights the potential of Bayesian LSS reconstructions for cosmology and is helpful in establishing them as a widely used technique.

ACKNOWLEDGMENTS

We thank Andreas Faltenbacher and Jeremy Blaizot for very useful discussions about the distribution of density fields and galaxy formation. Some of the plots in this paper have been done using the \textsc{healpix} (Górski et al. 2005) package. We also thank Samuel Leach for encouraging conversations and helping substantially with the sky plots using \textsc{healpix}. Moreover, we thank Rainer Moll, Martin Reinecke, Hans-Werner Paulsen and Heinz-Ado Arnolds for their inestimable computational support.

The authors thank the Intra-European Marie Curie fellowship and the Transregio TR33 Dark Universe, as well as the Munich cluster \textit{Universe} for supporting this project and both the Max Planck Institute for Astrophysics in Munich and the Scuola Internazionale Superiore di Studi Avanzati in Trieste for generously providing the authors with all the necessary facilities.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society and the Higher Education Funding Council for England.

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, University of Cambridge, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory and the University of Washington.

We finally thank the German Astrophysical Virtual Observatory (GAVO), which is supported by a grant from the German Federal Ministry of Education and Research (BMBF) under contract 05 AC6VHA, for providing us with mock data.
